Accepted 27 June, 2014

#### Abstract

This research involved general covering percentages in four locations (Bikher Mountain, Benarink Mountain, Derke Mountain and Gara Mountain) of Duhok governorate during the spring of 2009. Three central points were allocated in each elevation at south and north aspects. The elevations comprised from 600 masl up to 1300 masl. The highest mean of covering percentage for the studied area was recorded for herbs (27.13\%), followed by trees (21.93\%), rocks (13.72\%), grasses (13.47\%), litter ( $10.38 \%$ ), soil ( $8.91 \%$ ), and finally the lowest covering percentage recorded was for shrubs ( $4.47 \%$ ). The south aspect recorded the highest mean values (14.69, 27.19 and 4.63 ) for grasses, herbs and shrubs percentages respectively as compared to the north aspect ( $12.25,27.06$ and 4.131 ), but was only significant in grasses percentage. On the other hand, the north aspect recorded the highest mean values for trees, litter, bare soil, and rocks percentages as compared to the south aspect, but the differences were not significant except for trees percentage. The highest grasses percentage was recorded in higher altitude of 1100 and 1200 masl ( 15.25 and $15.0 \%$ ) and significantly differed with other elevations except 700 masl, and the lowest value was recorded in mid elevation of 800 masl which was $12.0 \%$. In contrast, the highest herbs percentage was recorded in the lowest altitude at 600 masl which was $34.50 \%$ and significantly differed with other altitudes especially 1300 masl which recorded the lowest value of $22.75 \%$. The highest mean value of trees ( $29.25 \%$ ) was recorded at elevation of 1200 masl, and significantly differed with other elevations especially at 600 masl ( $11.5 \%$ ), but the highest percentage of shrubs was recorded at mid altitude ( $9.5 \%$ at 900 masl) compared to lowest value of $2.5 \%$ at 600 masl. Bare soil and rocks percentages were the highest in lower altitude of $12.25 \%$ and $17.75 \%$ in 600 masl respectively and significantly differed with other altitudes (except the 700 masl).

Key words: Duhok governorate, mountain, south, north, elevation.

## INTRODUCTION

It was written by Holechek et al. (2004) that the productivity of the rangeland is determined by the characteristics of the soil, topography, and climate. Furthermore, the vegetation cover in mountainous areas is of great importance in many aspects including local and regional climate and erosion reduction (Brang et al., 2001). At the scale hill slopes, the principal limiting factor in vegetation growth is topography; but the soil types and the amount of rainfalls play secondary (Dawes and Short, 1994). The main topographic factors that influence the distribution and patterns of vegetation in mountain areas are elevation, aspect and slope (Titshall et al., 2000). Among these factors, elevation is the most important one (Busing et al., 1992). In many respects, elevation along
with aspect and slope determine the microclimate and thus large-scale spatial distribution and patterns of vegetation (Allen and Peet, 1990; Busing et al., 1992).
The effect of abiotic factors on distribution and patterns of vegetation growth have been studied by many researchers (Endress and Chinea, 2001; Bai et al., 2004). Biodiversity preservation is essential for the maintenance of stable productivity in ecosystems (Tilman and Downing, 1994). The rangelands in Iraqi Kurdistan region which lies between $34^{\circ} 31^{\prime} 30^{\prime \prime}$ and $37^{\circ} 22^{\circ} 50^{\prime \prime}$

[^0]latitude, and $41^{\circ} 17^{\circ} 00^{\prime \prime}$ and $46^{\circ} 20^{\circ} 00^{\prime \prime}$ longitude is one of the most important source of pastureland in Iraq as it possesses a huge biodiversity (Qassim, 1981; Besifky, 1999), which is very important for ecosystem and human wellbeing. Such great role that biodiversity plays in the ecosystems functioning ways and in the services they provide in several aspects include provisioning services, regulating services, cultural services, and supporting services (Cunningham et al., 2005).
Few researches have been conducted for estimating and evaluating the rangelands of this area (Al-kittany et al., 1978; Qassim, 1981; Toma, 1983; Besifky, 1999). Accordingly, the present study planned to achieve further benefits through identifying grasses and herbs species existing in the study area, thereby finding out their distributions and covering percentages in relation to the elevations and aspects; and thus compare between the different elevations, aspects and locations in order to evaluate the rangeland conditions for getting better realistic conceptions of establishing livestock projects and national parks (Exclosures) for wildlife re-habitation and protection.

## MATERIALS AND METHODS

## Study area

This study was carried out in the spring of 2009 at Duhok governorate which lies on Kurdistan Region, Iraq. The area is bounded by latitudes $36^{\circ} 50^{-} .00$ and $37^{\circ} 02^{-} .00 \mathrm{~N}$, and longitudes $42^{\circ} 50^{-} .00$ and $43^{\circ} 22^{-} .00 \mathrm{E}$.
The range of elevation in this study was from 550-1350 masl. The study area is mountainous and contains forest rangelands which are very rich of variety species including grasses and forbs such as species of Poaceae, Fabaceae, Asteraceae, Brassicaceae, Apiaceae and many other families, in addition to trees and shrubs such as Quercus aegilops, Quercus infectoria, Quercus libani, Wendlandia ligustroides, Anagyris foetida, Prunus microcarpa, Pistacia mutica, Pistacia khinjuk, Crateagos azarolus and other species.
The four locations that have been selected in the preceded area for recording observations were: 1) Bikher Mountains, 2) Benarink Mountains, 3) Derke Mountains and 4) Gara Mountains. In each location, two different elevations in the contrasted slope aspects (South and North aspects) were used for taking samples. About 100 $m$ differences in elevation was used to separate each of the two elevations of the contrasted slope aspect in every location. Three plots were allocated in each elevation of the contrasted slope aspects.
The elevations that have been selected for each location were:

1. 600 and 700 masl of north and south aspects at the first location.
2. 800 and 900 masl of north and south aspects at the
second location.
3. 1000 and 1100 masl of north and south aspects at the third location.
4. 1200 and 1300 masl of north and south aspects at the fourth location.

## Field work

Tapes were driven from the centre of each plot ( 55 m ) to three different directions with an angle of $120^{\circ}$. This process was used for studying the covering percentages in general (grass, herb, tree, shrub, rock, litter or bare soil percentages) according to the Line-point intercepts method (Elzinga et al., 2001) (Figure 1).
The spatial location (latitude, longitude and altitude) of each plot was measured by using a Global Positioning System device GPS (eTrex Vista ${ }^{\text {TM }}$ ) GARMIN Ltd. 20012002.

## Sampling

It was recorded (for grasses, herbs, trees, shrubs, rocks, litter, or bare soil) at every 0.5 m intercept interval along the transect line by dropping a pin flag freely (the pin flag is simply a piece of one meter long rod supplied with a pair of light), for all transect lines, to fulfill one hundred records for every transect line. The starting point of each transect line is 5 m far from the plot's centre.

## Soil samples

The mechanical and chemical properties of soil samples were tested according to Jackson (1958), and are shown in Table 1.

## Statistical analysis

Factorial experiment in randomized complete block design was applied for every location separately to estimate the effect of aspect, elevation, and their interactions on general covering percentage.

The effect of locations, aspects and their interactions on general covering percentages were also analyzed, in addition to the effect of elevations on general covering percentages, utilizing Statistical Analyses System (SAS) version 6.2 (2001). The treatment means were verified using Duncan's (1955) multiple ranges test (DMRT) at $p$ $=0.05$ significant level.

## RESULTS AND DISCUSSION

The data of the general covering percentages are represented in Table 3. The mean values of the covering percentage for the studied area in descending order from the highest mean value to the lowest are as follows: herbs ( $27.13 \%$ ), trees ( $21.93 \%$ ), rocks ( $13.72 \%$ ), grasses ( $13.47 \%$ ), litter ( $10.38 \%$ ), bare soil ( $8.91 \%$ ), and finally

Figure 1. Diagram showing line-point intercepts method (Elzinga et al., 2001).

the lowest covering percentages recorded was for shrubs (4.47\%).

Table 4 revealed that the highest percentage was recorded for grasses at altitudes 1100 and 1200 mas ( 15.25 and $15 \%$ respectively) and they significantly differed with other elevations, with the exception of 700 masl, and the lowest value was recorded in mid elevation (800 masl) which was $12 \%$. In contrast, the highest herbs percentage was recorded at the lowest altitude ( 600 masl) which was $34.50 \%$ and it significantly differed from other altitudes especially 1300 masl which recorded the lowest value of $22.75 \%$. These results were due to the fact that there is more grazing pressure in lowest elevations causing reduction of grasses as more palatable and lifting herbs compared to slight grazing in mid and higher altitudes.
The highest mean value of trees ( $29.25 \%$ ) was recorded at elevation 1200 masl and it significantly differed from other elevations especially at 600 mas ( $11.5 \%$ ). However the highest percentage of shrubs was recorded at mid altitude ( $9.5 \%$ at 900 masl) as compared to the lowest value of $2.5 \%$ at 600 masl. This is due to availability of more moisture at higher altitude which led to greater growth of trees in size and overriding shrubs' species, thus reducing their numbers, as well as the high human and grazing pressures in lower altitudes.
Bare soil and rocks percentages were highest in the lowest altitude ( 12.25 and $17.75 \%$ respectively), and they differed significantly from other altitudes (except the 700 masl). These were intuitive results according to over cutting of trees and shrubs and the continuous over grazing in the lowest elevation, which led to bare soil and consequently exposing it to more erosion. With respect to locations affecting cover traits at the same extent of elevations (Table 5), every two successive elevations represented a location; the first two elevations represented the first location, and the second two elevations represented the second location.
The results displayed in Table 5 showed that the south aspect recorded the highest mean values for grasses, herbs, and shrubs percentage (14.69, 27.19 and 4.63 respectively) as compared to the north aspect (12.25, 27.06 and 4.131 respectively) but they were only significant in grasses percentage. On the other hand, the north aspect recorded the highest mean values for trees, litter, bare soil, and rocks percentages as compared to the south aspect. However, the differences were not significant except for the trees percentage. These results were due to the availability of more moisture in the north aspect causing more trees growth in account of shrubs. The interactions of aspect-elevation are shown in Table 6:

- First location: The highest percentage of grasses (16\%) was recorded in south at 700 masl but it significantly differed from that of the north at 600 masl combination only. The highest percentages of herbs, soil, and rocks
were recorded in the south at 600 masl combination and the lowest percentages were recorded in the north aspect at highest elevations in general. In contrast, trees and shrubs percentages were higher in the north aspect at 700 masl combination, due to high human pressure and livestock grazing in the south aspect of the first location, which led to more soil erosion in the south aspect.
- Second location: There were no differences for grasses, herbs, and bare soil percentages between interactions, but trees percentage was highest in lower elevation. Rocks percentage was higher at the north aspect at 900 masl because it was less protected by trees and more exposed to water erosion.
- Third and fourth locations: There were no significant differences between all combinations for grasses, shrubs, and rocks percentages in the third location, but there were significant differences in the fourth location for herbs, trees, bare soil, and rocks percentages. The differences were little but significant for other traits and seemed to be inconsistent because of favorable environmental factors, as it was in the second location, and the slight differences found could be due to specific features and microclimate that characterize the positions of collecting data.

The aspect interaction effects of locations were displayed in Table 7. The highest percentages of grasses, herbs, bare soil and rocks were recorded in the first location at south aspect; meanwhile, the lowest percentage of trees and shrubs significantly differed from most of the interactions. These results clearly reflect the effect of moisture (precipitations) as shown in Table 2. The higher altitude observed in the over cutting of trees for fuel and grazing pressure in low elevations is as a result of more canopy cover in the third and fourth locations than in the first and second locations. The grasses and herbs' percentages declined in the third and fourth locations due to more competition on sunlight which made it obscure for it to reach the ground. These results were in harmony with those of Joseph et al. (2008) and Sharma et al. (2009).

It can be concluded that the south aspect had positive influence on grasses percentage in contrast to the north aspect for trees. Contrary to herbs percentage, the trees percentage increased with altitudinal increment. Grasses and litter percentages were inconsistently affected by elevations. The shrubs percentage was enhanced by the elevation up to 900 masl, thereafter it declined with elevation increment.
This study recommends the utilization of new technology, such as GIS, remote sensing to study the trend of the vegetation cover in the rangeland, in relation to such factors involved in this study, regarding elevations, aspects and slope degree. Further studies are required to determine the influence of microclimate on plant communities' characters. Moreover, there is need to study the seed mass distributions.

|  | North | 12.25 C | 23.25 D | 27.75 AB | 3.250 CD | 10.25 ABC | 6.500 E | 14.00 BC |

Different letters at the same column refer to signification at $\mathrm{p}=0.05$ according to DMRT (1955).

New laws and legislation have to be issued properly for land utilization taking into consideration the number and distribution of the livestock adequately on the rangelands. The proper carrying capacity for few years for every pasture used for grazing livestock should be determined, although it will vary from season to season due to inconsistent average rainfall. Determination of grazing intensity at different elevations and aspects at each location is also necessary. More so, there should be reseeding of uncovered areas with nutritive and palatable species for collection of seeds from species around these areas. Nonetheless, some national parks (Exclosures) should be established for wildlife re-habitation and protection, because of the great support, provisioning, regulation and cultural benefits they provide.
